21 Abstract

Various treatment approaches have been determined efficacious for improving child 22 behavior outcomes. Despite a variety of evidence-based options, consumers often disregard 23 empirically supported treatments to pursue alternatives that lack empirical support, 24 e.g. fad therapies. The choice to pursue therapies lacking empirical support has been 25 considered as a 'gamble' on the rapeutic outcomes and this form of risky choice has 26 historically been explained using various cognitive heuristics and biases. This report translates quantitative analyses from the Operant Demand Framework to characterize how caregivers of children with behavioral issues consume treatment services. The operant demand framework is presented, its utility for characterizing patterns of treatment consumption is discussed, and a preliminary application of cross-price analyses of demand is performed to illustrate how various factors jointly influence treatment-related choice. Results indicated that caregivers endorsing interest in receiving behavioral parent training regularly pursued pseudoscientific alternatives as a functional substitute for an established 34 therapy, despite explicit language stating a lack of evidence. These findings question the 35 presumption of rationality in models of treatment choice as well as the degree to which 36 scientific evidence influences the consumption of therapies. This report concludes with a 37 discussion of Consumer Behavior Analysis and how quantitative analyses of behavior can be used to better understand factors that enhance or detract from the dissemination of 39 evidence-based practices.

Applications of Operant Demand to Treatment Selection I: Characterizing Demand for Evidence-based Practices

46 Introduction

The APA Presidential Task Force on Evidence-Based Practice (2006) has defined 47 Evidence-based Practices (EBPs) as "...the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences (p. 273)." Broadly, a focus on EBPs reflects a commitment to align clinical services with the approaches and procedures that are most supported by credible and scientific evidence (Newsom & Hovanitz, 2015). In the context of developmental and child behavior issues, 52 various practices have been determined to be empirically supported for improving specific 53 outcomes (Chambless et al., 1998; National Autism Center, 2015). Although highlighted here in the context of child behavior therapies, it warrants noting that commitments to EBPs are typically observed in most clinical fields, including pediatrics (American Academy of Pediatrics, 2017), speech and language pathology (American 57 Speech-Language-Hearing Association, 2005), and healthcare more broadly (Evidence-Based Medicine Working Group, 1992).

"Alternatives" to Evidence-based Practices

Not all practices marketed to families experiencing undesired child behavior are supported by strong evidence (i.e., complementary and "alternative" treatment options).

Practices marketed to caregivers may lack scientific evidence of efficacy, or worse, have a documented risk of harm (Food and Drug Administration, 2019). Such dangerous and questionable services exist for the treatment of various developmental and behavioral disorders; however, these tend to be marketed most heavily towards families of children diagnosed with Autism Spectrum Disorder (ASD; Travers et al., 2016). Indeed, the range of "fad" and pseudoscientific services marketed to the ASD population and their families

has been considerable and has included practices such as Auditory Integration Training
(Dawson & Watling, 2000), Sensory Integration Therapy (Lang et al., 2012), various
mineral supplements and dietary restrictions (Trudeau et al., 2019), chelation therapy
(Davis et al., 2013), hyperbaric oxygen therapy (Jepson et al., 2011), and Facilitated
Communication (Mostert, 2001), along with its derivative, the Rapid Prompting Method
(Hemsley, 2016).

The proliferation of practices lacking strong evidence is not a recent development 75 and these alternatives to EBPs have previously been described in ways such as "scientifically questionable" treatments (Lilienfeld, 2005), as "fads" or "controversial" treatments (Foxx, 2008), or as forms of pseudoscientific thinking outright (Normand, 2008). Regardless of the specific term used to describe the consumption of these practices, each refers to an instance where services are pursued despite a limited degree (or total lack) of scientific evidence. These services are marketed heavily towards families of children with 81 developmental and behavioral disorders and often result in families adopting such practices at levels that exceed (or completely replace) EBPs (Green et al., 2006). Put simply, these 83 alternative approaches seem to be consumed as if they were equivalent or superior replacements to EBPs (i.e., functional substitutes). This alarming trend is also reflected in 85 professional decision-making, with educators of children in early childhood (Stahmer et al., 2005) and the public school system (Hess et al., 2008) endorsing high levels of these practices as well.

89 (A)Rational Treatment Choice

The enduring demand for alternative therapies that lack scientific support naturally evokes questions regarding the factors that drive treatment choices. Rational assumptions hold that decision-makers would allocate greater resources to the prospects that have the greatest likelihood of returns. EBPs are more associated with positive and reliable returns, and thus, should be consumed most readily and at higher levels. Viewing caregivers and

families as consumers and treatments as investments in future health and wellness, classical economic assumptions hold that agents should respond in ways that maximize their expected utility or benefit (Strotz, 1955). Per classical economic reasoning, the rational actor should disregard inferior prospects that are associated with suboptimal or questionable benefits (i.e., poor return on the resources invested). However, deviations from these "rational" choices are quite common (Ainslie, 1974, 1992) and this perspective, Rational Choice Theory (RCT), fails to account for these phenomena. Specifically, RCT succeeds in describing how agents should make choices (i.e., to maximize utility) but fails to predict how agents actually make choices.

Revisiting choice in the context of selecting behavior therapies, let us apply RCT to 104 a hypothetical agent selecting from one of several treatment options for addressing their 105 child's undesirable behavior. In this scenario, the choice is between an established EBP 106 (e.g., applied behavior analysis) and some alternative that clearly lacks scientific support 107 (e.g., a "fad" or pseudoscientific behavior therapy). The rational agent would scrutinize the 108 strength and degree of support for each form of therapy and it stands to reason that they 109 would choose the option associated with higher levels of efficacy (e.g., improvements in 110 behavior). However, revisiting the concerns noted above, RCT and assumptions of 111 rationality provide a better description of how we should behave but serve as a poor 112 framework for predicting how individuals actually make choices. As such, this calls into 113 question whether differences in the degree of scientific evidence influence choices in child 114 behavior therapies. 115

Factors Associated with "Alternative" Treatment Choices

Researchers have explored how various factors contribute to the consumption of alternative (i.e., suboptimal) treatment approaches. Smith (2015) highlighted various strategies used to advertise the purported benefits of these approaches. Specifically, vendors of these approaches often use language that obscures the actual, likely effect(s) of

the treatment. For example, the language included in these advertisements often includes vague and non-specific indicators of improvement that are difficult or impossible to 122 quantitatively refute (e.g., increased "focus", "attending"). Additionally, these practices 123 use language that emphasizes ease and immediacy, which are contrasted with EBPs that 124 generally entail substantial time, effort, and resources to implement as designed. As such, 125 the emphasis here is placed not on evidence (i.e., treatment efficacy) but instead on ease 126 and immediacy—dimensions of reinforcement associated with greater efficacy and relative 127 preference. It warrants noting that reinforcer efficacy and treatment efficacy are distinct 128 concepts, with treatment efficacy representing distal effect(s) of treatment choices (e.g., 129 child behavior improvement, outcomes) and reinforcer efficacy the proximal contingencies 130 related to implementation (i.e., immediate consequences of implementation). 131

Beyond the use of vague and misleading language, Foxall (2004) posited that 132 consumption can be maintained by a convergence of multiple reinforcement contingencies. 133 Consumer Behavior Analysis highlights the relevance of both Utilitarian (UR) and 134 Informational Reinforcement (IR) contingencies (Foxall, 2001). Briefly, UR contingencies 135 closely relate to the traditional definition of reinforcement whereby the putative effect on 136 behavior is a direct result of consuming the reinforcer (e.g., edible reinforcers). 137 Alternatively, IR contingencies represent those mediated by members of the verbal 138 community as a function of consuming specific goods or services (e.g., signaling status). To 139 better illustrate the two, let us consider the social contingencies (informational) that differ 140 when consuming economy versus luxury clothing. Controlling for size and features, both 141 economy and luxury clothing offer comparable utilitarian contingencies because, 142 functionally, they both provide the same direct result (i.e., protection from elements, 143 warmth). However, the two differ in informational contingencies because the consumption of premium and luxury goods is much more associated with greater levels of recognition and 145 praise by the verbal community. Revisiting child behavior treatment, various "fads" (e.g., fidget spinners) demonstrate spurious effects on behavior (i.e., low utilitarian value) but

165

166

167

members of the verbal community often recognize and praise such patterns of consumption
(e.g., status signaling, both in-person and via social media). Viewed across these
dimensions, "alternative" treatment practices may not require any degree of utilitarian
value (i.e., efficacy) at all to reach and sustain high levels of consumption and adoption.

52 Elucidating "Alternative" Treatment Choice

Experimental research with human and non-human animals has developed and 153 applied procedures that elucidate deviations from maximized utility, i.e. "irrational" choices (Ainslie, 1974; Ainslie & Herrnstein, 1981). Experimental methods emerging from 155 Operant Behavioral Economics have revealed that organisms regularly deviate from 156 rational choices and tend to demonstrate a relative preference for immediate and lesser 157 prospects over optimal ones, which are typically delayed and may be uncertain. This 158 phenomenon, discounting, is one of several frequently evaluated in the Operant Behavioral 159 Economic framework (Hursh, 2014; Reed et al., 2013). Discounting has been explored in 160 the context of various treatment choice situations, such as the choice of whether or not to 161 pursue vaccination (Jit & Mibei, 2015), to continue or discontinue effective behavior 162 therapy (Swift & Callahan, 2010), and whether to disregard optimal, but delayed behavior 163 management strategies (Gilroy & Kaplan, 2020). 164

Methods designed to elucidate patterns of suboptimal choice (i.e., discounting) typically present choices to participants in a dichotomous manner (e.g., larger, later vs. smaller, sooner).

In these procedures, prospects vary across one or two dimensions (e.g., delays, magnitude) and this is highly effective for isolating the effects of certain aspects of choice.

However, choices take place in complex arrangements and the dichotomous nature of this

¹ We note here that Consumer Behavior Analysis is a highly related perspective that is also subsumed under the greater Operant Behavioral Economic framework.

format fails to account for the relations that may exist between reinforcers (e.g., complementary, substitutional relations; Hursh, 1980). For instance, consider the treatment 172 programming for a young child diagnosed with ASD. Caregivers of children diagnosed with 173 this disorder typically report consuming a wide range of different behavior therapies. 174 concurrently, each to varying degrees (Goin-Kochel et al., 2007; Green et al., 2006). In a 175 survey of caregiver treatment choices, Green et al. (2006) found that caregivers of children 176 with ASD, on average, endorsed the use of up to eight behavior therapies at a time. Given 177 that treatment choices are rarely dichotomous (i.e., just Treatment A or just Treatment B) 178 and because relations likely exist between treatments, the discounting framework fails to 179 account for the possible interactions that might exist between treatment choices. 180

Within the Operant Behavioral Economic framework, the demand methodology 181 provides a means of analyzing patterns of consumption under various constraints, e.g. time, 182 limited resources (Hursh, 1980; Kagel & Winkler, 1972; Rachlin et al., 1976). Rather than 183 presenting choices as dichotomous (i.e., which treatments), consumption is indexed 184 continuously across alternatives (i.e., how much of each treatment). In a hypothetical 185 experiment related to treatment choice, a caregiver might endorse the consumption of 186 Therapy A for five hours/week on average, Therapy B for four hours/week on average, and 187 Therapy C for one hour a week on average—each consumed at a different price. The 188 Operant Demand Framework supports an analysis of how pricing, the availability of 189 alternatives, and various other factors influence the consumption of certain services (e.g., 190 EBPs). 191

Operant demand methods are well-suited to characterizing the consumption of
behavior therapies for several reasons. First, researchers can evaluate the bliss point
consumption of specific goods or services. That is, the consumer's overall level of demand,
if the price was no object, can be modeled directly and used as an index of its hedonic
value (Hursh & Silberberg, 2008). This is useful for comparing the demand for specific
services across individuals and arrangements (e.g., EBPs, recommended treatments).

Additionally, researchers can evaluate how strongly consumers would defend their levels of 198 consumption of services when prices increase or when other treatment alternatives become 199 available (Hursh, 2000). When we speak of defending consumption, we refer to the degree 200 to which the consumer remains committed to their base level consumption of some 201 treatment service before either ceasing that consumption (i.e., terminating therapy) or 202 substituting that consumption with some alternative (e.g., fads, alternative therapies). For 203 instance, a high level of demand would indicate that agents were willing to endure the 204 burden of high costs to maintain their base levels of EBP consumption. Alternatively, a 205 low level of defense would mean that agents quickly decrease/cease their consumption of 206 EBPs when relatively minor increases in price/effort are encountered. This response is 207 captured in models via a rate parameter in the demand curve (Gilroy et al., 2020; Hursh & 208 Silberberg, 2008). For convenience, the original Exponential model of operant demand outlined in Hursh and Silberberg (2008) is listed in Equation 1 below: 210

$$log_{10}Q = log_{10}Q_0 + k(e^{-\alpha Q_0 P} - 1)$$
(1)

In this exponential decay model, consumption (Q) is modeled as a function of price 211 (P). As mentioned previously, Q_0 represents the bliss point and the α parameter reflects 212 the rate of change in elasticity standardized to the level of the intercept. The range of 213 consumption is constrained by the parameter k. In addition to characterizing the demand 214 for behavior therapies, the operant demand approach can be used to quantify relationships 215 that exist between different types of commodities and how they are consumed in tandem 216 (Hursh et al., 2013). For example, decision-makers may consume certain treatments together (i.e., the treatments complement one another), consume certain treatments only 218 as a replacement to others (i.e., one treatment substitutes the other), or the consumption of treatments may be completely independent of one another (Hursh & Roma, 2016). Such 220 relationships are particularly useful for characterizing choices for behavior intervention 221 because it is unclear how caregivers arrive at specific combinations of behavior treatment.

For instance, this approach can be used to quantify how families consume and defend their consumption of EBPs in the presence and absence of "alternatives" that differ in levels of empirical evidence or treatment efficacy. Similarly, this approach can be used to determine whether "alternative" treatments are consumed as substitutes to EBPs, as complements, or if the consumption of the two appears to occur independently of each other.

8 Research Goals

The purpose of this study was to provide a preliminary demonstration of how the 229 Operant Demand Framework can be used to evaluate factors associated with the consumption of child behavior therapies (e.g., EBPs, alternative treatments). Specifically, 231 the goal of this demonstration was to evaluate whether caregivers would pursue alternative 232 treatments (i.e., no evidence) as if they were functional substitutes to EBPs. Two 233 Hypothetical Treatment Purchase Tasks (HTPTs) were developed in this study to evaluate 234 the consumption of treatments when each varied in terms of their level of supporting 235 evidence. Methods from operant demand were applied to quantify the patterns of 236 consumption observed when EBPs were available alone (closed economy) and accompanied 237 by an alternative therapy (open economy). The overall demand for EBPs was evaluated 238 alone as well as with cross-price analyses to quantify the relationship between EBPs and 230 alternative therapies (e.g., complements, substitutes). 240

241 Methods

2 Participants

243

244

245

A total of 63 caregivers of children reporting child behavior concerns as well as interest in pursuing parent-mediated behavioral therapy were recruited using the Amazon Mechanical Turk platform (MTurk). Briefly, MTurk is a crowdsourcing platform where "workers" (i.e., participants) meeting requisite criteria complete various tasks for

"requesters" (i.e., researchers) and are compensated for their work (Chandler & Shapiro,
248 2016). The task was made available to workers on the MTurk platform if they met the
249 following criteria: 1) completion of at least 1,000 total tasks; 2) maintained an overall 99%
250 approval rating for their submitted work; 3) and resided in the United States. These
251 requirements are consistent with recommended practices for gathering "crowdsourced"
252 participant data (Chandler & Shapiro, 2016). Eligible workers completed a survey designed
253 using the Qualtrics Research SuiteTM.

254 Criteria for Inclusion

All study methods and instruments were approved by the Louisiana State 255 University Institutional Review Board. The initial portion of the research instrument 256 evaluated whether the caregivers were eligible to participate. Prospective participants had 257 to have been caring for at least one school-aged child in a custodial role and endorsed some 258 level of concern regarding their child's behavior (i.e., enough to consider behavior therapy). 250 Caregivers endorsing that they either had no children, no child behavioral concerns, or no 260 interest in pursuing parent-mediated child behavior therapies were subsequently informed 261 that they were not eligible to participate in the study. Once detendividual worker IDs were logged and screened from subsequent batches). After the survey, participants who completed all measures were provided with a unique string which was then submitted to the MTurk portal to complete the HIT and received a \$1.00 payment for the approximately 265 10 min task, i.e. consistent with recommended payment guidelines; see Chandler and 266 Shapiro (2016).

268 Systematicity of Demand Data

Responses collected using the MTurk platform were evaluated for indicators of systematic responding (i.e., non-random patterns of choice). Criteria for systematic responding on Hypothetical Purchase Task data were first proposed in Stein et al. (2015)

and these were designed to assess three indicators of systematic demand data. First, 272 "trend" refers to the global direction of consumption and the expected form of 273 consumption is a decreasing trend as prices increase (i.e., from low to high prices). Second, 274 "bounce" refers to the local direction of consumption as prices increase. That is, 275 consumption should not be low at one price only to be followed by high consumption at the 276 next highest price. Third, "reversals from zero" speak to instances where non-zero 277 consumption is reported after zero consumption is endorsed at a lower price. That is, it 278 would be unexpected to consume 0 service units at \$100/hour and then subsequently 279 report consumption of 2 service units at \$250/hour. These indicators were assessed using 280 methods included in the beezdemand software package (Kaplan et al., 2019) in the R 281 Statistical Program (R Core Team, 2017). These indicators of responding provide a level of 282 data validation when using crowdsourced data.

Hypothetical Treatment Purchase Task (HTPT)

Caregivers eligible to participate in the study completed two HTPTs—one with 285 EBPs available alone and another with EBPs accompanied by a mock Alternative Therapy 286 (EBP+AT). In each HTPT, participants were allotted a hypothetical budget of up to 287 \$5,000 per week to spend towards child behavior services with a maximum of 20 hours 288 available for treatment. The overall budget and price points were formed around an 280 approximated hourly rate of 200 USD. Participants were informed that if they did not 290 spend the funds on treatment the remaining money could not be directed elsewhere or 291 saved. Similarly, both treatments were described as parent-training programs and each was 292 framed in terms that indicated equal effort and time commitments. In both HTPTs, the 293 prices per unit (i.e., hour of service) for the EBP were \$50, \$100, \$150, \$200, \$250, \$300, \$400, \$500, \$750, \$1000, \$2000, \$3000, and \$5000 per hour. Prices for the EBP were identical across both the EBP and the EBP+AT HTPTs.

$_{297}$ Alone-Price Demand for EBPs (EBP HTPT)

The EBP HTPT was designed to elucidate caregiver choice when only EBPs were 298 available. The EBP presented here was derived from established behavioral principles of 299 punishment and reinforcement (see Appendix). The vignette presented to the participant 300 explicitly stated that the EBP was strongly supported by empirical research and caregivers 301 were instructed to imagine that their child's primary care physician would highly 302 recommend this approach based on credible and scientific evidence. Alone-price demand 303 for EBPs was assessed across each of the prices listed in the section above. At each price 304 point, participants could elect to spend as much or as little time and money toward these services as they preferred or could afford. If participants endorsed preferences beyond those constraints (e.g., over 20 hours, over \$5,000) they were subsequently prompted to spend within their budget before they could proceed to the next price point or task.

309 Own-Price Demand for EBPs (EBP+AT HTPT)

The EBP+AT HTPT was designed to evaluate patterns of choice across EBPs and 310 ATs. This task included the same prices, budget, and EBP from the EBP HTPT but also 311 featured an AT option that was available at a fixed price (\$100/hour). That is, both an 312 EBP and an AT were concurrently available in any combination desired by the caregiver. 313 The AT described here was a mock pseudoscientific treatment termed "Positive 314 Attachment Therapy." In addition to the vignette for the EBP, a second vignette was 315 presented to the caregiver specific to the AT (see Appendix). In this vignette, the AT was 316 described as a therapeutic approach for challenging behavior using "therapeutic embrace" 317 as the underlying mechanism of behavior change-similar to the basis for Gentle Touch (Bailey, 1992). Additionally, the vignette explicitly stated that the AT did not have 319 scientific evidence supporting its use, and caregivers were instructed to imagine that their 320 child's primary care physician recommended against this approach due to its lack of 321

scientific evidence. Consistent with the EBP HTPT, participants could spend as much time and/or money towards treatment(s) given time and cost constraints.

324 Analytical Plan

Caregiver consumption of EBPs and FPTs across both HTPTs was evaluated using 325 the Zero Bounded Exponential (ZBE) model of demand (Gilroy et al., 2021) in a 326 mixed-effects modeling approach (Kaplan et al., 2021). Briefly, the ZBE model is an 327 extension of the original Exponential model of operant demand (Hursh & Silberberg, 2008) with a modified scale (Inverse Hyperbolic Sine) that optionally supports a true lower 329 bound at zero consumption. Specifically, the ZBE model has a form to accommodate 330 non-zero lower asymptotes (i.e., not at zero; Equation 2), zero asymptotes (i.e., reaching 331 true zero; Equation 3), and when demand is purely inelastic (i.e., demand essentially flat; 332 Equation 4). Each variant exists in the same scale (IHS) and models can be evaluated 333 using traditional model selection procedures (e.g., Sum of Squares F-test). Specifically, Eq. 334 3 and Eq. 4 were considered restricted forms of Eq. 2 and the complexity of the final 335 model was determined before performing further analysis. The various forms of the ZBE 336 model are illustrated below: 337

$$IHS(Q) = IHS(Q_0) + k(e^{-\alpha Q_0 P} - 1)$$
 (2)

$$IHS(Q) = IHS(Q_0) * e^{-\frac{\alpha}{IHS(Q_0)}Q_0P}$$
(3)

$$IHS(Q) = IHS(Q_0) \tag{4}$$

The ZBE model was used to evaluate a participant's consumption in units of therapy (Q) as prices (P) ranged from low to high. In this framework, the span of the demand curve $(k \text{ [Eq. 2] or } Q_0 \text{ [Eq. 3]})$ reflects the range of modeled consumption in IHS units and this was determined via parameter estimation. Parameter Q_0 reflects the overall intensity of demand as prices approach a price of zero (and potentially the full span; Equation 3) and α is an index of the rate of change in elasticity. In contrast to the Exponential model of demand, α can be normalized in units of Q_0 to support comparisons in the absence of an explicit span parameter (Gilroy et al., 2021). Unless noted otherwise, all model fitting was performed using the R Statistical Program (R Core Team, 2017) using the *nlme* package (Pinheiro et al., 2014). All analytical syntax and study data have been included as supplemental materials and are hosted in a repository managed by the corresponding author, see Author Note.

50 Alone-/Own-Price Demand for EBPs

The alone- and own-price demand for EBPs was evaluated using the ZBE model of 351 operant demand. Model selection was performed using the levels of reported consumption 352 across prices for all participants. The best-performing model was then evaluated using a 353 generalized nonlinear least squares and multilevel modeling approach (Pinheiro et al., 354 2014) to evaluate the influence of various covariates (e.g., gender, income). Although 355 measures of demand elasticity (η) may be determined via differentiation (Gilroy et al., 356 2020), elasticity for each fitted model was determined by optimizing the peak levels of 357 responding on the natural scale (Gilroy et al., 2021). This quantity (P_{MAX}) was then 358 multiplied by the predicted levels of demand at this point (\hat{Q}) to yield the peak 350 expenditure on EBPs (O_{MAX}) for both HTPTs. 360

Cross-Price Demand for ATs

361

Demand for EBPs and ATs was evaluated with two different strategies. First, the
own-price demand for EBPs was evaluated in the same manner as the alone-price demand
approach listed above. Second, Hursh and Roma (2013) previously provided a form of the
Exponential model that evaluates the cross-price elasticity of demand for alternatives.

However, this approach was not used in this evaluation. Rather, a Generalized Estimating

Equation (GEE) was used to evaluate how various covariates beyond price contribute to the consumption (or non-consumption) of ATs. The GEE procedure was selected over the 368 Hursh and Roma (2013) approach for several pragmatic reasons. First, the GEE strategy is 369 flexible and can be adapted to evaluate various factors (e.g., price, demographics) that may 370 be related to reported consumption (i.e., covariates). Second, GEE is similar to multilevel 371 models and is often applied in experiments to account for repeated measurements across 372 individuals (Hardin, 2005; Kaplan & Koffarnus, 2019; Kaplan et al., 2020). Such an 373 approach avoids issues associated with ordinary least squares regression, e.g., 374 non-independence (DeHart & Kaplan, 2019; Kaplan et al., 2021). Third, similar to the 375 methods proposed in Hursh and Roma (2013), the quantity regressed upon price in the 376 GEE approach captures the direction and rate of changes in consumption as the price to 377 consume EBPs changes. For instance, a weight of zero ascribed to Price would indicate no changes in AT consumption as prices to consume EBPs increased (i.e., services appear to 379 be consumed independently). Alternatively, a non-zero value would indicate that the consumption of ATs changed in a particular direction in response to changes in the price 381 for EBPs. Specifically, a positive value would indicate that the consumption of ATs 382 increased while EBPs decreased (i.e., substitute) and a negative value would indicate the 383 contrary (i.e., complement). Additionally, the fitted intercept represents an indicator of the 384 AT's baseline hedonic value. Lastly, the GEE approach fares better in cases where the span 385 parameter I in the Hursh and Roma (2013) approaches zero, and the reciprocal nature of 386 the I and β parameters occasionally leads to highly inflated and questionable estimates. 387

The cross-price demand for ATs was evaluated using GEE with an exchangeable correlation structure and model comparisons were performed using the QIC metric included in the *MuMin* R package (Barton, 2015). Briefly, the QIC value is an indicator frequently used to select the best-performing model and correlation structure when comparing various modeling options in GEE (Pan, 2001). As noted in Pan (2001), the QIC metric is derived from the Akaike Information Criterion (AIC; Akaike, 1974) but has been modified to

support GEE because this procedure is not based on maximum likelihood estimation.

395 Results

Alone-Price Demand for EBPs (EBP HTPT)

Table 1
Participant Demographics

Participant Demographics $(n = 63)$					
Age (years)		Number of Children			
Mean (SD)	38.1 (9.52)	Median (Q1-Q3)	2 (1-2)		
Median (Q1-Q3)	38 (30-43.5)	Mean (SD)	1.79 (0.92)		
$\underline{\mathbf{Sex}}$		Education	•

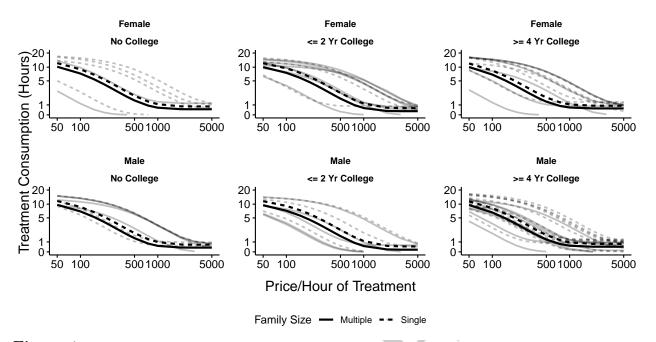

Figure 1

Alone-Price Demand for Evidence-based Practices

A total of 63 participants completed the survey and 54 met all criteria for 397 systematic purchase data across both HTPTs (100%). The demographics of included 398 participants are listed in Table 1. The alone-price demand for EBPs using mean 399 consumption levels was evaluated using each of the ZBE models prior to analysis. Model comparisons revealed that the 3-parameter ZBE model better characterized the data than the two-parameter (F/1,816)=23.02, p<0.001) and one-parameter alternatives (F/2,816)=23.02402 816/=339.14, p<0.001). The 3-parameter form of the ZBE model was used to estimate Q_0 403 and α across reported levels of education (no college, some/junior college, 4+ year degree), gender (male, female), and family size (single, multiple children). The separate span 405 parameter was estimated globally, and thus, shared across all participants. The analysis 406 was performed with both the full data set and the portion of the data set that met all 407 criteria for systematic purchase data. There were no meaningful differences in 408 interpretation and the results of the regression with the full data set are listed in Table 2 409 and displayed in Figure 1. Model fits indicated a main effect for the number of children, 410

whereby caregivers caring for a single child reported significantly higher baseline levels of EBP consumption than others with multiple children $(Q_0[Single] = 2.949, T = 2.156, p <$.05). Population-level predictions revealed a peak expenditure (O_{MAX}) of 1,007 USD towards EBPs, which occurred at a price (P_{MAX}) of 371.11 USD per unit hour of therapy.

Own-Price Demand for EBPs (EBP/AT HTPT)

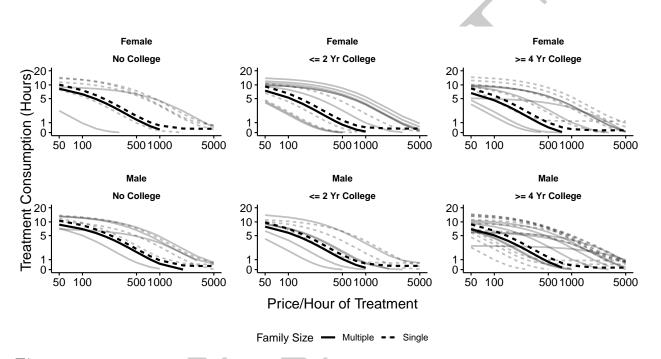

Figure 2

Own-Price Demand for Evidence-based Practices

Model comparisons revealed that the 3-parameter form of the ZBE model better characterized own-price demand for EBPs than the two-parameter (F[1, 816] =7.43, p=0.007) and one-parameter alternatives (F[2, 816]=294.78, p<0.001). The 3-parameter form of the ZBE model was used to estimate Q_0 , α , and k parameters in the same manner as in the Alone-Price demand for EBPs. Similar to the previous analysis, the full data set was analyzed because the inclusion of non-systematic purchase task data did not affect the conclusions supported by the model. The results of this regression are listed in Table 2 and displayed in Figure 2. Model fits revealed a main effect for the number of children, whereby

caregivers caring for a single child reported significantly higher baseline levels of EBP consumption than others with multiple children $(Q_0[Single] = 2.224, T = 2.03, p < .05)$.
Population-level predictions revealed a peak expenditure (O_{MAX}) of 1094 USD towards
EBPs, which occurred at a price (P_{MAX}) of 427.94 USD per unit hour of therapy.

428 Cross-Price Demand for ATs (EBP/AT HTPT)

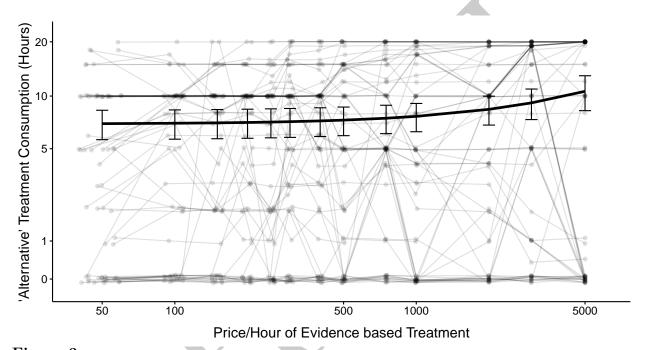

Figure 3

Cross-Price Demand for Alternative Therapy

The GEE was applied using the geeglm method included in the geepack R package 429 (Halekoh et al., 2006). Factors in the GEE fitting included Price (of EBP), Gender (Men, 430 Women), Family Size (Single, Multiple Children), and Education (i.e., No College, ≤ 2 431 Yr College, >= 4 Yr College) and all possible interactions. Model selection using QIC 432 favored the model with Price as the sole factor associated with the consumption of ATs 433 $(\beta[Price] = 0.001, W = 26.2, p < .0001)$. That is, no demographic factors were 434 significantly related to levels of AT consumption. The results of this analysis are illustrated 435 in Figure 3. The results of this analysis indicated that caregivers, overall, demonstrated a 436

452

453

454

455

456

substitutive relationship between EBPs and ATs. Specifically, caregivers overall indicated
that they would consume higher levels of ATs if they were unable to maintain their baseline
level of EBP consumption.

440 Discussion

Terms such as "evidence-based" and "empirically-supported" are labels used to 441 identify therapies and approaches found to be efficacious or at least probably efficacious 442 (Chambless et al., 1998). These designations aid in communicating the relative efficacy of 443 specific treatments as well as in advocating for the use of these approaches over dubious alternatives. However, despite an established body of evidence supporting EBPs, "fad" and pseudoscientific therapies maintain high levels of adoption. Indeed, certain "alternative" therapies have persisted for decades despite a consistent lack of support, and worse, those 447 discredited following careful scientific study have re-emerged at later times in re-branded forms.² Given the relatively limited value associated with being labeled as having scientific evidence (i.e., evidence-based), this prompts further inquiry into the factors that influence 450 consumer choice for treatment. 451

This experimental preliminary study applied an Operant Behavioral Economic interpretation of treatment choice when multiple behavior therapies were concurrently available to caregivers. The approach used here is novel in that it permits researchers to evaluate how certain forms of treatment consumption relate to one another. Preliminary results indicated that caregivers regularly and overwhelmingly reported that they would pursue "alternative" therapies as functional substitutes for EBPs, despite being told explicitly that the "alternative" lacked credible evidence that it would provide benefit.

² Interested readers should consult Travers, J. C., Ayers, K., Simpson, R. L., & Crutchfield, S. (2016). Fad, pseudoscientific, and controversial interventions. In *Early intervention for young children with autism spectrum disorder* (pp. 257-293). Springer. for a review of the decline and return of Facilitated Communication.

Even further, participants were told to imagine that their child's physician actively advocated against it. Throughout the experiment, scientific evidence of efficacy did not emerge as a factor that swayed consumers from "alternative" treatments.

Although unsettling, this pattern of consumption (i.e., substituting ATs with EBPs) 462 is consistent with an Operant Behavioral Economic view of individual choice. That is, 463 findings from behavioral science have found that caregivers rarely commit to the most optimal prospects and instead make choices based on delay to treatment effects (Call, Reavis, et al., 2015; Gilroy & Kaplan, 2020) or prior treatment experience (Call, Delfs, et al., 2015). That is, scientific evidence has rarely emerged as the primary factor that drives treatment-related choices made by caregivers. Although studies such as Call, Delfs, et al. (2015), Gilroy and Kaplan (2020), and Call, Reavis, et al. (2015) have arrived at similar findings, these works have applied either a descriptive or a discounting-based approach to 470 evaluate this manner of decision-making. Here, we advocate for the use of the Operant 471 Demand Framework over other methodologies for several reasons. First, this approach is 472 well-suited to represent the complex and rapidly changing landscape of services available to 473 consumers. Results indicated that the overall demand for EBPs decreased by a 474 considerable 30% when just one AT was available, and it is plausible that this difference 475 might be exacerbated when multiple ATs are concurrently available. The approach used 476 here can be extended to evaluate overall patterns and trends in service use when a variety 477 of treatment approaches are available. Second, demand curve analyses support the 478 evaluation of consumption as a function of price (as well as other relevant factors), and 479 results from these analyses may be useful in guiding future policy related to behavior 480 therapies (Hursh & Roma, 2013). For example, the demand methodology could be used to 481 evaluate which pricing arrangements most support the consumption of efficacious 482 treatments (i.e., EBPs) and discourage the use of unsafe, ineffective, and predatory 483 alternatives (i.e., ATs). Findings here indicated that the availability of a single fad or 484 "alternative" treatment substantially decreased the baseline consumption of EBPs (~12

units @ 50 USD/hr) when compared to when EBPs were available alone (~17 units @ 50 486 USD/hr). This empirical approach to public policy has been demonstrated in the use of 487 targeted taxes to discourage unhealthy choices, such as ultraviolent tanning (Reed et al., 488 2016) and cigarette use (MacKillop et al., 2012; Pope et al., 2020), and to encourage 489 sustainable practices (e.g., "green" consumerism, Kaplan et al., 2018). However, it 490 warrants noting that further refinement of this approach will be necessary before such an 491 approach would be helpful to inform healthcare policies. That is, the purpose of the 492 current study was an initial investigation into whether the demand framework could be 493 applied to the societally important issue of treatment consumption and subsequent works 494 in this area will need to expand on this application. To move towards more direct policy 495 implications, future purchase tasks would need to use more informed pricing structures, 496 budgets tailored to individual households, and additional treatment offerings that are more representative of what is currently marketed to caregivers.

Findings from this study evoke questions regarding how to advocate most effectively 499 for EBPs and discourage the use of unproven, and potentially unsafe, ATs. Current 500 attempts to educate or persuade caregivers against ATs focus heavily on consulting the 501 research literature; however, reviews of evidence alone appear unlikely to convince 502 caregivers to allocate their resources (or even a proportion of resources) towards EBPs. As 503 most clinicians would likely attest, advocating for EBPs is not so simple as stating "... but 504 the research says" and future attempts to advocate for EBPs warrant a more sophisticated, 505 targeted approach based on principles of reinforcement. Indeed, emerging methodologies 506 such as Consumer Behavior Analysis (Foxall, 2017; Foxall et al., 2007; Foxall et al., 2010) 507 hold particular promise in evaluating how multiple dimensions of behavioral contingencies 508 jointly influence the consumption of specific goods and services.

Limitations 510

Although the interpretation provided here is consistent with behavioral economic 511 concepts and methods, it warrants noting that this study serves as a preliminary 512 demonstration and several potential limitations must be discussed. First, the primary 513 purpose of this demonstration was to determine whether cross-price analyses of demand 514 could be adapted to evaluate the relationships between multiple treatment options. 515 Whereas the current approach was sufficiently powered to answer questions related to the 516 relationship between treatment options, this demonstration was not sufficiently powered to 517 detect small, but potentially meaningful effects associated with covariates beyond Price. Although the single-stage analysis performed here is more powerful than traditional 519 two-stage methods (Kaplan et al., 2021), larger and more powerful designs will be necessary when research questions focus on how factors beyond price influence 521 consumption on these types of tasks (e.g., level of education, income). Second, the 522 vignettes included in this HTPT were designed to produce a context in which most 523 caregivers consulted an individual qualified to interpret scientific evidence (i.e., child's 524 pediatrician). Although this avenue is broadly relatable, caregivers regularly receive 525 information regarding child behavior therapies from various sources (e.g., social media, 526 neighborhoods; informational contingencies). As such, additional evaluation using methods 527 and concepts derived from Consumer Behavior Analysis could be beneficial in further 528 extending the breadth of contingencies that support these choices. Notwithstanding these 529 limitations, this study represents a successful, preliminary application of the Operant 530 Demand Framework to how caregivers make treatment-related choices for their children. 531
